Intracellular Ca$^{2+}$ Regulation During Neuronal Differentiation of Murine Embryonal Carcinoma and Mesenchymal Stem Cells

Rodrigo R. Resende,1,2 José L. da Costa,3 Alexandre H. Kihara,4,5 Avishek Adhikari,6 and Eudes Lorençon1

Changes in intracellular Ca$^{2+}$ concentration ([Ca$^{2+}$]$_i$) play a central role in neuronal differentiation. However, Ca$^{2+}$ signaling in this process remains poorly understood and it is unknown whether embryonic and adult stem cells share the same signaling pathways. To clarify this issue, neuronal differentiation was analyzed in two cell lines: embryonic P19 carcinoma stem cells (CSCs) and adult murine bone-marrow mesenchymal stem cells (MSC). We studied Ca$^{2+}$ release from the endoplasmic reticulum via intracellular ryanodine-sensitive (RyR) and IP$_3$-sensitive (IP$_3$R) receptors. We observed that caffeine, a RyR agonist, induced a [Ca$^{2+}$]$_i$ response that increased throughout neuronal differentiation. We also demonstrated a functional coupling between RyRs and L- but not with N-, P-, or Q-type Ca$_{1.2}$ channels, both in embryonal CSC and adult MSC. We also found that agonists of L-type channels and of RyRs increase neurogenesis and neuronal differentiation, while antagonists of these channels have the opposite effect. Thus, our data demonstrate that in both cell lines RyRs control internal Ca$^{2+}$ release following voltage-dependent Ca$^{2+}$ entry via L-type Ca$^{2+}$ channels. This study shows that both in embryonal CSC and adult MSC [Ca$^{2+}$]$_i$ is controlled by a common pathway, indicating that coupling of L-type Ca$^{2+}$ channels and RyRs may be a conserved mechanism necessary for neuronal differentiation.

Introduction

Calcium signaling has many physiological roles [1] including intercellular signaling [2], proliferation [3], apoptosis [3], control of gene expression [4], and release of bioactive molecules such as neurotransmitters [5,6] due to calcium influx from voltage-gated Ca$^{2+}$ channels (VGCCs) [7]. Interestingly, Ca$^{2+}$ influx through VGCCs, such as long-lasting Ca$^{2+}$ channels (L-type, also known as Ca$_{1.2}$), also affects the expression of genes involved in cell proliferation, programmed cell death, and neuronal differentiation [8–11]. Considering that calcium is involved in this multitude of processes, it is not surprising that intracellular Ca$^{2+}$ concentration ([Ca$^{2+}$]$_i$) is controlled by multiple mechanisms. Calcium influx may occur through membrane channels as well as through intracellular stores such as the endoplasmic reticulum (ER). Release of Ca$^{2+}$ from the ER is simultaneously controlled by ryanodine receptors (RyRs) [12] and inositol-1,3,4-triphosphate receptors (IP$_3$R) [13], and counterbalanced by the activity of Ca$^{2+}$ pumps such as sarco/endoplasmic reticulum Ca$^{2+}$-ATPase (SERCA) [14].

Calcium influxes through these intracellular stores may participate in neuronal differentiation, a process in which the role and pathways of Ca$^{2+}$ signaling have been extensively investigated and modeled [15–19]. However, it is not clear whether particular Ca$^{2+}$ pathways are cell-line-specific or if there are common processes in the neuronal differentiation of diverse cell lines. We thus characterized Ca$^{2+}$ signaling in stem cell lines as distinct as embryonal carcinoma stem cells (CSC) and adult murine bone-marrow mesenchymal stem cells (MSC), to identify conserved events in the control of cell proliferation and differentiation. We have previously shown that P19 embryonic CSC express functional VGCCs, which produce Ca$^{2+}$-induced Ca$^{2+}$ release (CICR) through a combination of L-type Ca$^{2+}$ channels and RyRs and IP$_3$Rs activity [19,20]. We now report that the RyR agonist caffeine produces a transient increase in Ca$^{2+}$ that
becomes larger throughout neuronal differentiation both in CSCs and MSCs. Moreover, these Ca2+ transients are blocked by L-type Ca2+-channel blockers, suggesting that RyRs and L-type Ca2+ channels are coupled. Our data also show that agonists of both of these channels increase neurogenesis and differentiation into neurons in CSCs and MSCs, while antagonists of these channels block these processes. Thus, this report suggests that coupling of L-type Ca2+ channels and RyRs is a mechanism that may be conserved in neuronal differentiation in diverse stem cell lines, and the IP3Rs have a major role in induction of neuronal differentiation beyond the RyRs.

Materials and Methods

Reagents

Unless indicated otherwise, all reagents were purchased from Sigma (Sigma, St. Louis, MO). Appropriate secondary biotin conjugate antibodies were used at 1/200 dilutions (Santa Cruz Biotechnology, Heidelberg, Germany). Primers for real-time PCR were synthesized by Integrated DNA Technologies (Coralville, IA).

Culture and neuronal differentiation of CSC cells

P19 EC cells were grown in DMEM (Invitrogen Corp., Carlsbad, CA) supplemented with 10% of final volume with fetal bovine serum (FBS; Cultilab, Campinas, Brazil), 100 units/mL penicillin, 100 μg/mL streptomycin, 2 mM sodium pyruvate, and 2 mM L-glutamine in a humidified incubator at 5% CO2 and 37°C. One micromolar of all trans-retinoic acid (RA) was used for neuronal differentiation induction. P19 cells were cultured in suspension to induce the formation of embryonic bodies (EB) in bacterial culture dishes coated with 0.2% of final volume with agarose for 48 h at a density of 5 × 106 cells/mL in defined serum-free medium as described previously [18,19,21,22]. Glial cell growth was suppressed by treatment with 50 μg/mL cytosine arabinoside on day 6 of differentiation.

Isolation and culture of sphere-derived cells from murine bone marrow

All experiments in this study were performed in accordance with the Animal Protection Guidelines of University of São Paulo. Bone-marrow cells (BMCs) were obtained from five mice for each experiment as previously described [23]. Briefly, bone marrow was collected from 2-month-old C57Bl/6 mice by flushing femurs and tibias with complete medium constituted of Dulbecco’s modified Eagle’s medium (DMEM), 10% fetal calf serum (FCS; Sigma, St. Louis, MO), 2 mM glutamine and 50 U/mL penicillin, 50 μg/mL streptomycin supplemented with heparin at a final concentration of 5 U/mL. Cells were then washed twice in a heparin-free medium and plated in a Petri dish at a density of 2 × 106 cells/cm2. After 2 days, nonadherent cells were removed by two to three washes with phosphate-buffered saline (PBS) and adherent cells were further cultured in complete medium for four supplementary days. To remove differentiated hematopoietic cells, these cells were depleted from whole BMCs by means of immunomagnetic separation with Dynabeads according to the manufacturer’s protocol. Briefly, BMCs were stained with primary rat–anti-mouse antibodies, namely anti-CD4, CD8, CD11b, CD45R/B220, Gr-1, and Ter119 (all purchased from PharMingen, San Jose, CA). After centrifugation of the labeled cells, Dynabeads M-450 Sheep anti-Rat IgG (Dynal Biotech, Oslo, Norway) were added at a concentration of 10 beads per cell. The mixture was placed on a Dynal Magnetic Particle Concentrator (Dynal Biotech) for 1 min and the supernatant containing the line-depleted BMCs was collected. Immunodepleted BMCs were resuspended in 10 mL of complete medium and plated on a 35 × 10 mm tissue culture dish (NUNC, Naperville, IL). Cells were cultured in a humidified incubator containing 5% CO2 and 5% O2 at 37°C. After 24 h, nonadherent cells were removed by washing with PBS and a fresh complete medium was added. Afterwards, the medium was changed twice a week for 3–4 weeks, when cells first reached 70–80% confluence. Then, adherent cells were detached with trypsin/EDTA for 3 min at 37°C. Only easily detached cells were plated on a 35 × 10 mm standard tissue culture dish (first passage). After the first passage, cells were cultured under similar conditions, except that the split ratio was set to 1:2. After additional 5–7 passages, cells were detached at a lower cell density (40–50% confluence). The same conditions were used for subsequent cultures after small round and oval-shaped cells had become predominant by the sixth to eighth passage.

A total of 1 × 105 cells was suspended in complete medium in each well of a six-well ultra low attachment plate (NUNC, Naperville, IL). Cells were cultured without having the medium changed, and were rotated gently every 6 h. The spheres gradually increased in size and, 7 days after suspension, were picked and dissociated mechanically by gentle pipetting. Dissociated cells were cultured in complete medium on standard tissue culture dishes and the medium was changed every 2 days. After reaching 40–50% confluence, cells were detached with trypsin/EDTA and replated at 1:4 dilution. Sphere-derived cells were harvested for the experiments described below when a single well of the original culture contained >1 × 104 cells.

In order to induce neuronal differentiation, sphere-derived cells were treated as previously described [24] with some modifications. Briefly, cells were plated at a cell density of 1 × 104 cells/cm2 on gelatin-coated dishes in neurobasal medium (Gibco BRL, Grand Island, New York) with B27 Supplement (5×; Invitrogen Corp., Carlsbad, CA), 20 ng/mL EGF, and 10 ng/mL bFGF for 7 days, followed by culture in neurobasal medium with 0.5 μM retinoic acid and 20 ng/mL β-NGF for 5 days.

Immunofluorescence studies

For immunofluorescence, cells were fixed in 1% paraformaldehyde (PFA), permeabilized with 0.2% Triton X-100 in PBS at 4°C for 30 min, blocked with 0.5% casein and 5% normal goat serum in PBS at 4°C for 30 min, and sequentially incubated with anti-nestin (1:200; Chemicon International Inc., Temecula, CA) or NEL (1:100; Santa Cruz Biotechnology Inc., Delaware, CA, USA) antibodies at 4°C overnight, followed by incubation with secondary antibodies coupled with cytochrome 3 (Cy3, 1:200; Jackson Immunoresearch, West Grove, PA) at room temperature (RT) for 1 h. Between each step, cells were washed three times with 0.1% Tween in PBS. Fluorescence was detected and photographed with an AxioCam photomicroscope (Carl Zeiss).
Vision GmbH, Hallbergmoos, Germany). The immunofluorescent staining of a single sphere was performed as previously described [25].

Confocal [Ca\(^{2+}\)] imaging

[Ca\(^{2+}\)] was measured in single cell as previously described [19,21,22]. The undifferentiated and differentiating cell cultures were incubated with 2.5 μM Ca\(^{2+}\)-sensitive dye Fluoro-3-AM (dissolved in DMSO) plus 0.02% Pluronic F-127 (dissolved in water; Molecular Probes Inc., Eugene, OR) in DMEM medium supplemented with FBS for 30 min at 37°C. The osmolarity of all the solutions ranged between 298 and 303 mosmol/L. Measurements of [Ca\(^{2+}\)] were performed at 37°C in extracellular medium (EM) containing (in mM): 140 NaCl, 3 KCl, 1 MgCl\(_2\), 2.5 CaCl\(_2\), 10 HEPES, pH 7.4, 10 glucose with the Zeiss Microscope Photometer System (FP; Carl Zeiss Optronics GmbH, Oberkochen, Germany), based on an inverted microscope (Axiovert 100; Zeiss). Fluoro-3 AM fluorescence was excited with a 488 nm line of an argon ion laser, and the emitted light was detected using a bandpass filter at 515–530 nm. Fluorescence values were corrected for background and dark current. Calcium imaging was performed with a LSM 510 confocal microscope (Carl Zeiss Jena GmbH, Jena, Germany), using image sizes of 256 × 256 pixels and acquisition rates of one frame per second. The calibration of the fluorescence signal, in terms of free Ca\(^{2+}\) concentration, was based on the procedure described by Grynkiewicz and collaborators [26]. At the end of each experiment, 5 μM ionophore (4-Br-A23187) was followed by 10 mM EGTA to determine F\(_{\text{max}}\) and F\(_{\text{min}}\) fluorescence values, respectively. The average baseline fluorescence was normalized to F\(_{\text{min}}\) as previously described [19,21]. To evaluate the contribution of VGCC activation to the studied Ca\(^{2+}\) signals, the depolarizing stimuli were delivered in the presence of the nonselective VGCC blocker Cd\(^{2+}\) (250 μM). Before testing the effects of Cd\(^{2+}\), the stability of [Ca\(^{2+}\)] responses to depolarizing stimuli repeated at 5-min intervals was evaluated. The amplitude of the ΔF/F ratios in response to the first four stimulations remained fairly stable; those of the third and fourth transients were, respectively, 4.9 ± 2.3 % (n = 45) and 8.5 ± 2.1 % (n = 37) smaller than that of the first.

The role of Ca\(_{1}\)-mediated Ca\(^{2+}\) influx in promoting neuronal differentiation of neuronal progenitor cells (NPC) derived from CSC and MSC was also investigated. Depolarization-induced Ca\(^{2+}\) transients were studied in cells cultured in defined medium with the addition of either 5 μM nifedipine or 10 μM Bay-K, a specific L-type channel blocker and an activator, respectively. Control cells were cultured in medium containing the same concentration of ethanol present in dihidropiridine (DHP)-treated cultures. Before being used in Ca\(^{2+}\)-imaging experiments, cells were repeatedly washed and subsequently subjected to a 10-min drug-washout perfusion with DHP-free solution to prevent any acute effects of DHP on the signals being studied.

For calcium imaging in Ca\(^{2+}\)-free extracellular medium, cells were treated for 1 min with Ca\(^{2+}\)-free medium containing 1 mM EGTA. Control measurements in the presence of extracellular Ca\(^{2+}\)-containing medium were performed before and after experiments in Ca\(^{2+}\)-free medium. All antagonists were preincubated with CSCs or MSCs for, at least, 20 min before experiments were performed.

**Western-blot assays**

NPC from day 6 derived from CSC and MSC were homogenized in ice-cold lysis buffer containing protease inhibitors, 10 mM Tris-HCl (pH 7.5), 8 M urea, 20 mM EDTA, 150 mM NaCl, 1% Triton X-100. Forty micrograms of membrane proteins that were fractionated by differential centrifugation, separated by SDS-PAGE, and transferred to nitrocellulose membranes were used. The procedure of incubation with primary and secondary antibodies was essentially the same as described previously [18,21]. The following polyclonal rabbit antisera were used: anti-nestin (1:200), anti-neuronal enolase (NEL, 1:300), anti-SSEA-1 (1:100; Santa Cruz Biotechnology, Heidelberg, Germany), and anti-β-actin (1:400). β-actin protein expression was used as internal standard for relative quantification of nestin and NEL expression levels.

**RNA isolation, reverse transcription, real-time PCR, and conventional PCR**

Total RNA was isolated using TRIzol (Invitrogen Corp., Carlsbad, CA) from undifferentiated cells and from days 2 to 8, following the induction of neuronal differentiation in the presence of RA for CSC and in the presence of RA and β-NGF for MSC. Additional RNA was extracted on the sixth day of neuronal differentiation that had been cultured for 48 h in the presence or absence of 5 μM nifedipine or 10 μM Bay-K. Integrity of the isolated RNA was verified by separation of an aliquot of the extracted RNA on a 2% ethidium bromide-stained agarose gel. DNA was removed from RNA samples by incubation with DNase I (Ambion Inc., Austin, TX).

Three micrograms of total RNA were reverse transcribed to cDNA with 200U of RevertAid H Minus M-MuLV reverse transcriptase (Fermentas Inc., Hanover, MD). DNA templates were amplified by real-time PCR on the 7000 Sequence Detection System (ABI Prism; Applied Biosystems, Foster City, CA) using the Sybr green method [19,22] or were amplified by PCR and analyzed as described previously [18,19,22]. Variations in cDNA concentrations were normalized with β-actin as an internal control, which is a constitutively expressed gene. Experiments were performed in triplicate for each data point. Primer sequences for reverse transcription and quantitative PCR amplification (qRT-PCR) of β-actin, IP\(_{\text{Rs}}\) and RyRs isoforms mRNA and for PCR amplification (RT-PCR) of β-actin, nestin, and NEL cDNA used in this study are listed in Table 1. Negative controls were conducted on water and on total RNA nonreverse transcribed. To evaluate the specificity of the RT-PCR products, they were gel-purified, cloned into PGEM T-Easy vectors (Promega, Madison, WI), sequenced, and confirmed to be identical to mouse NEL and nestin cDNA.

**Proliferation assays**

5-Bromo-2-deoxyuridine (BrdU; Amersham Life Sciences, Arlington, IL, EUA), a pyrimidine analog, was used to determine the synthesis rate of DNA and to perform an incorporation assay. Twenty-four hours prior to proliferation stimulation, NPC were kept in serum-free medium. They were then maintained for 8 h in culture medium in the presence or absence of 1 μM ryanodine (Rya E)C, acts as an activator of ryanodine-sensitive calcium stores) or 10 μM
ryanodine (Rya InhC, an inhibitor of ryanodine-sensitive calcium stores), which were co-applied with or without agonists or inhibitors of receptor-induced calcium signal transduction. BrdU (15 μM) was then added to the cell culture and kept for an additional hour. Cell proliferation was detected by using an anti-BrdU monoclonal antibody (Molecular Probes Inc., Eugene, OR) monoclonal antibody for 1 h at room temperature. After washing with PBS, BrdU/NEL, or BrdU/nestin, stained cells were examined by fluorescence microscopy [18,21].

Statistical analysis

Data are represented as means ± SEM of five or more independent experiments (each with two replicates). The peak amplitude of [Ca$^{2+}$] increase/response is represented in the bar diagrams with mean ± SEM. Statistical significance was determined by Student’s t-test or one-way ANOVA plus a post-hoc Tukey’s test. Values of $p < 0.05$ were considered as statistically significant.

Results

Resting [Ca$^{2+}$], levels

Basal [Ca$^{2+}$] levels were 31 ± 3.9 nM in embryonic CSCs ($n = 101$) and 72 ± 8.4 nM in the eighth day of neuronal-differentiated CSCs ($n = 98$). For undifferentiated MSCs, basal [Ca$^{2+}$] levels were 47 ± 5.7 nM ($n = 86$) and 102 ± 12.6 nM after neuronal phenotype acquisition ($n = 74$). Under resting conditions, the basal (resting) [Ca$^{2+}$] levels in these differentiating cells varied, depending on the day of culture, from 51 ± 5.0 nM (CSC, $n = 48$) and 62 ± 6.7 nM (MSCs, $n = 57$) on the fourth day after RA or RA and β-NGF addition, respectively, to 74 ± 9.8 nM ($n = 64$) and 87 ± 10.1 nM ($n = 72$) on the sixth day. Although small variations of the

Table 1. Primers for Amplification of IP$$_3$$Rs and RyR Receptor Subtypes by Real-Time and Conventional PCR
resting [Ca^{2+}], levels were observed, no clear correlation could be found with the number of days cells were in culture. Data pooled from days 0 to 8 were scattered around a mean value of 57 ± 6.8 nM (CSC, n = 52) and 74 ± 8.8 nM (MSC, n = 61).

**Gene expression of RyR and IP₃R isoforms during neuronal differentiation**

We next studied gene expression of IP₃R and RyR isoforms during neuronal differentiation of CSCs and MSCs. At 8 days in vitro, among the three RyR isoforms, only RyR3 was detected in significant levels, in CSCs and MSCs, respectively. All three IP₃R isoforms were detected, although IP₃R type 1 and 2 mRNA expressions were very weak in CSCs and MSCs, respectively (Fig. 1). Real-time PCR revealed that gene expression of IP₃R 1, 2, and 3 subtypes was already present in embryonic CSCs and adult MSCs, remaining at a lower level during initial and intermediate differentiation states and increasing significantly when differentiating cells became post-mitotic and underwent final maturation on days 6–8 (Fig. 1).

**[Ca^{2+}], responses induced by caffeine increase during neuronal differentiation**

Caffeine (10 mM), which in millimolar concentrations acts as an inhibitor of intracellular receptors for IP₃, as well as an activator of RyRs [31], was applied for 10 s on undifferentiated and differentiated cells from the fourth day (when

![Graphs showing gene expression of RyR and IP₃R isoforms during neuronal differentiation.](image)

**FIG. 1.** Quantification of the different isoforms of ryanodine (RyR) and inositol-1,4,5-triphosphate (IP₃R) receptor mRNA transcription during neuronal differentiation of carcinoma (CSC) and mesenchymal (MSC) stem cells by real-time PCR. Gene expression levels of receptor subtypes were normalized to the internal control β-actin. The graphs show RyR and IP₃ mRNA transcription levels in differentiating cells compared to those in undifferentiated cells which were normalized to zero. Cells on Day 8 of differentiation were pretreated on Day 6 with cytosine arabinoside, in order to avoid contamination of the cell cultures with glial cells. The data shown are mean values ± SEM of at least five independent experiments in triplicate. In some cases, the error bar is included within the symbol. *p < 0.05 compared with control data.
calcium transients, which increased progressively across days (Fig. 2).

Spontaneous \([\text{Ca}^{2+}]_{\text{i}}\) oscillations were observed under resting conditions or after a brief application of caffeine throughout the differentiation. Neuronal-differentiated (eighth day) cells showed a mean \([\text{Ca}^{2+}]_{\text{i}}\), peak amplitude of about 2.6 ± 0.03 for CSC- and 3.6 ± 0.05 for MSC-derived neurons (DN). These responses were diminished when cells were incubated with 5 μM nifedipine (N- or P/Q-type \(\text{Ca}^{2+}\)-channel blockers had no effect—data not shown) or 1 μM thapsigargin (inhibitor of intracellular calcium stores), recovering to normal levels after washout of these drugs (data not shown).

**Caffeine- and CPA-specificity action**

Caffeine-induced \([\text{Ca}^{2+}]_{\text{i}}\), responses were initially tested in the presence of 10 μM ryanodine to verify the specificity of caffeine action on the \([\text{Ca}^{2+}]_{\text{i}}\) increases. Ryanodine at a concentration of 10 μM (ryanodine inhibitory, or Rya InhC) acts as an inhibitor of RyRs, while 1 μM ryanodine (ryanodine excitatory, or Rya ExC) excites RyRs. Neuronal-differentiated cells from the eighth day were used for this test. In control conditions, caffeine-induced \([\text{Ca}^{2+}]_{\text{i}}\), responses were (in nM): 1008 ± 50.4 and 957 ± 56.0 for CSC- and MSC-DN, respectively (data not shown). To avoid any additional \([\text{Ca}^{2+}]_{\text{i}}\), elevations ryanodine alone was applied for 2 min, inducing a very small increase in \([\text{Ca}^{2+}]_{\text{i}}\), to 105 ± 15.7 nM (CSC-DN) and 123 ± 10.2 nM (MSC-DN). After preincubation with RyA InhC, caffeine induced a very small \([\text{Ca}^{2+}]_{\text{i}}\) elevation in neurons derived from both, CSCs (\(\Delta[\text{Ca}^{2+}]_{\text{i}} = 47 ± 6.1 \text{nM}\)) and MSCs (\(\Delta[\text{Ca}^{2+}]_{\text{i}} = 164 ± 17.8 \text{nM}\)). No significant inhibition of \([\text{Ca}^{2+}]_{\text{i}}\), increases was obtained with the IP3R inhibitor XeC (10 μM) on both, CSC and MSC. These results indicated that RyA InhC inhibited caffeine-induced \([\text{Ca}^{2+}]_{\text{i}}\), responses.

In order to evaluate the specificity of CPA activity on intracellular calcium stores, XeC (10 μM) was used to inhibit IP3Rs and SERCA pumps (data not shown). CPA-induced \([\text{Ca}^{2+}]_{\text{i}}\), responses were of 242 ± 38.6 nM and 254 ± 27.2 nM on CSC-DN and MSC-DN, respectively, and these responses were practically absent when the culture cells were preincubated with XeC for 5 min (\(\Delta[\text{Ca}^{2+}]_{\text{i}}\) in nM: 17 ± 2.2 and 35 ± 10.7, respectively). The inhibition of the IP3Rs and the SERCA pumps responses caused by the presence of XeC was reversible as receptor responses recovered following washing out of the inhibitor (\(\Delta[\text{Ca}^{2+}]_{\text{i}}\) in nM: 234 ± 35 for CSC-DN and 242 ± 29 for MSC-DN).

**[Ca^{2+}]_{i} responses induced by \text{Ca},1 increase during neuronal differentiation**

To further characterize L-type \text{Ca},1 channel and RyR \([\text{Ca}^{2+}]_{\text{i}}\), responses, 10 μM Bay-K, an agonist of L-type channels, or 1 μM ryanodine (Rya ExC) were applied. Each drug
was applied for 30 s on CSC and MSC cells cultures during neuronal differentiation. L-type Ca,1 channel-induced [Ca^{2+}], responses increased during the differentiation process for both, CSCs and MSCs. The ∆[Ca^{2+}] in nM for embryonic CSCs was 148 ± 12.4, and for differentiating cells it was 303 ± 15.9, 694 ± 36.2, and 970 ± 36.8 at days 4, 6, and 8 after induction with RA. The response for undifferentiated MSCs was 226 ± 14.7, while it was 419 ± 11.1, 693 ± 18.2, and 885 ± 39.1 at days 4, 6, and 8 following induction with RA and β-NGF (Fig. 3A). As demonstrated for Bay-K application and confirming real-time PCR and caffeine-induced [Ca^{2+}], transients data, ryanodine-induced [Ca^{2+}], responses increased during the differentiation of CSC and MSC (∆[Ca^{2+}], in nM for: embryonic CSC, 179 ± 4.9; fourth day, 290 ± 70; sixth day, 723 ± 40.3; and 857 ± 34.8 at eighth day. And for MSC: undifferentiated MSC, 15 ± 1.8; fourth day, 290 ± 6.9; sixth day, 771 ± 40.6; and 939 ± 13.0 at eighth day (Fig. 3A).

To elucidate if RyR or L-type Ca,1 channel activation controls [Ca^{2+}], transients of each other, VGCCs were activated with 20 mM KCl and these responses were significantly inhibited by ryanodine InhC (Fig. 3B). Furthermore, [Ca^{2+}], transients mediated by 10 μM Bay-K were also significantly inhibited by 10 μM ryanodine (Fig. 3B). These results indicated that L-type Ca,1 channel-induced [Ca^{2+}], responses were mainly controlled by RyRs in neuronal-differentiated cells derived from CSC and MSC, with a minor role played by N-type channel for the latter.

**L-type Ca,1 channels are controlled by caffeine-induced [Ca^{2+}], responses**

The role of the various VGCCs expressed by neuronal-differentiated CSCs and MSCs cells on caffeine-induced [Ca^{2+}], responses was studied in order to evaluate the contribution of extracellular Ca^{2+} to neuronal differentiation. Blockers of VGCCs, such as nifedipine (for L-type Ca,1 channel), ω-CgTx (for N-type), and ω-MVIIC (for P/Q-type Ca,2 channels), were used to evaluate the participation of these channels in caffeine-evoked [Ca^{2+}], increases (data not shown). These VGCC blockers were preincubated with the cells for 15 min at room temperature in the dark prior to application of caffeine. The first application of caffeine evoked an increase of 1016 ± 55.6 nM and 892 ± 45.0 nM for CSC-DN and MSC-DN, respectively. Caffeine-induced [Ca^{2+}], responses were strongly reduced in the presence of 5 μM nifedipine in both, CSC-DNs and MSC-DNs (∆[Ca^{2+}], in nM: 246 ± 21.4 and 343 ± 15, respectively). The N-type channel blocker, ω-CgTx-GVIA (800 nM), and the P-type channel blocker, ω-MVIIC (100 nM), presented no effects on caffeine-induced [Ca^{2+}], responses in CSC-DNs (in the presence of ω-CgTx-GVIA, ∆[Ca^{2+}], = 1030 ± 46.6 nM; and in the presence of ω-MVIIC, ∆[Ca^{2+}], = 987 ± 49.7 nM, relative to control conditions ∆[Ca^{2+}], = 951 ± 62.7 nM). However, for MSC-DNs the N-type channel blocker promoted a significant reduction on [Ca^{2+}], elevations by caffeine (∆[Ca^{2+}], = 674 ± 111.7 nM, relative to control conditions ∆[Ca^{2+}], = 862 ± 36.6 nM).

**FIG. 3.** Functional characterization of L-type Ca,1 channel and RyR [Ca^{2+}], responses. (A) Amplitudes of ryanodine-(Rya Exc, 1 μM) and Bay-K (10 μM)-induced [Ca^{2+}], increases during neuronal differentiation of carcinoma (CSC) and mesenchymal (MSC) stem cells, respectively. Upper panel: Representative traces of [Ca^{2+}], responses of CSC cells after application of Rya and then with Bay-K. Lower panels indicate values of ∆[Ca^{2+}], increases obtained in the presence of Rya represented with white bars and then with Bay-K represented with gray bars. (B) Neuronal cells from day 8 of differentiation from CSC and MSC were induced with KCl (20 mM) or Bay-K (10 μM) and in the presence of absence of ryanodine (Rya InhC, 10 μM) or nifedipine (5 μM). Upper panels show a typical [Ca^{2+}], response observed in a neuronal cell derived from CSC from day 8 of differentiation. Lower panels: Average [Ca^{2+}], values from control conditions and in the presence of the respective inhibitors were plotted as ∆[Ca^{2+}], measurements. White bars represent CSC and gray bars represent MSC. Plots were typical of five independent experiments. The total number of cells analyzed in each experiment was 48–59. Data are presented as mean values ± SEM; *p < 0.05, **p < 0.001 compared with control data.
Role of L-type Ca\(^{2+}\) channels in inducing NPC cells differentiation

In order to investigate the role of Ca\(_{\text{v}1}\)-mediated Ca\(^{2+}\) influx in promoting neuronal differentiation of NPCs, cells from the fourth day of differentiation were cultured for 48 h in the presence of an antagonist (5 \(\mu\)M nifedipine) and of an agonist of L-type channels (10 \(\mu\)M Bay-K). The percentage of NEL-positive and nestin-positive cells, the percentage of cells exhibiting \([\text{Ca}^{2+}]_i\) transients in response to KCl stimulation, and the amplitude of the recorded signals were then determined. Confocal \([\text{Ca}^{2+}]_i\)-imaging experiments were performed after DHP washout.

The percentage of NEL-positive stained cells treated with nifedipine dropped 62% and 54% relative to control conditions for cells derived from CSC and MSC, respectively (Fig. 4A and Table 2). NEL-positive cells in Bay-K-treated cultures increased 36% and 23% relative to control for CSC- and MSC-DN, respectively. Similar effects were observed when NPC derived from CSC were stained for nestin (23% ± 4.1% of the cells cultured with nifedipine, 32% ± 3.0% of control cells, and 41% ± 3.4% of those cultured with Bay-K) and from MSC (23% ± 3.0% of the cells cultured with nifedipine, 31% ± 2.8% of control cells, and 38% ± 4.0% of those cultured with Bay-K) (Fig. 4A and Table 2). In agreement, nestin and NEL gene and protein expression were enhanced as revealed by RT-PCR and Western-blot experiments when NPC of CSC or MSC had been differentiated in the presence of either DHPs (Fig. 4B,C, see Table 2 for summary). These results suggest

![Graph A](image1.png)

**FIG. 4.** Ca\(_{\text{v}1}\)-mediated Ca\(^{2+}\) influx induces neuronal progenitor cells (NPCs) to differentiate into neuronal cells. NPCs from Day 4 of differentiation derived from carcinoma (CSC) and mesenchymal (MSC) stem cells were cultured for 2 days in the presence or absence of nifedipine (5 \(\mu\)M) or Bay-K (10 \(\mu\)M), and the percentage of nestin-positive (represented as gray bars) or NEL-positive (represented as dark-gray bars) cells was analyzed by immunofluorescence, counted, and plotted as a percentage of total cells (A). Gene (B) and protein (C) expression of NEL and nestin from NPC from CSC and MSC at the same conditions were also evaluated. The percentage of cells exhibiting \([\text{Ca}^{2+}]_i\) transients in response to KCl stimulation was determined (D) and the amplitude of the recorded signals was then evaluated (E).
that Ca\(_{1,1}\) channels also participate in induction of differentiation of NPC.

To quantitate cell proliferation, NPC on the fourth day were used in a BrdU assay. No significant differences were observed on BrdU incorporation between nontreated cells from CSC- and MSC-DN, even when cells were exposed to nifedipine or Bay-K (Table 2). Based on our analysis of 20–23 randomly selected 20 fields for each experimental condition, the total number of cells in control, nifedipine-, and Bay-K-treated cultures was not significantly different. These findings suggest that NPC proliferation in CSC and MSC are not significantly affected by either of the DHPs, suggesting a common role for the CSC and MSC differentiation and proliferation.

In Ca\(^{2+}\)-imaging studies performed on neuronal cells from the sixth day of differentiation, KCl stimulation caused very weak increases in fluorescence (\(\Delta F/F = 0.8 \pm 0.23\) and 1.0 \(\pm 0.42\), for CSC- and MSC-DN, respectively) when these cells were cultured with nifedipine, whereas those cells cultured in control conditions displayed signals with a mean amplitude of 1.9 \(\pm 0.29\) and 2.2 \(\pm 0.37\), for CSC- and MSC-DN, respectively. These were enhanced in the presence of Bay-K (2.5 \(\pm 0.31\) and 2.6 \(\pm 0.42\), i.e., 29% and 20% larger than in CSC- and MSC-DN controls, respectively) (Fig. 4D). The percentage of nifedipine-treated NPC cells responding to KCl stimulation was also significantly reduced 31% \(\pm 4.8\%\) and 38% \(\pm 7.5\%\), respectively. In contrast, in NPC cultured in the presence of Bay-K, [Ca\(^{2+}\)], transients were observed in 74% \(\pm 13.4\%\) and 78% \(\pm 10.7\%\) versus 43% \(\pm 6.4\%\) and 57% \(\pm 9.8\%\) of CSC- and MSC-DN controls, respectively (Fig. 4E).

Rya InhC, treatment with ryanodine at inhibitory concentration (10 μM); Rya ExC, treatment with ryanodine at excitatory concentration (1 μM); AdA, Adenophostin-A (2 nM); xestopongin C (XeC, 10 μM); Nifedipine was used at 5 μM, Bay-K at 10 μM, and KCl at 20 mM; (—) data not evaluated.

Data presented are means \(\pm\) SEM of positive-stained NPC for the neuronal enolase (a mature neuronal marker, NEL), nestin (a marker for NPC) and BrdU/NEL and BrdU/nestin double-labeling. * \(p < 0.05\), ** \(p < 0.001\).

No significant effect on cell viability evaluated by Tunel was observed on treated cells (data not shown), supporting the idea that a functional neuronal phenotype may be maintained via activation of L-type Ca\(_{1,1}\) channels.

RyR direct neural differentiation process to neuronal cell fate

To evaluate if the increased neuronal differentiation in NPC derived from CSC and MSC is directly related to RyR function, neuronal differentiation was analyzed by adding 1 μM (Rya ExC, which excites RyRs) or 10 μM ryanodine (Rya InhC, an inhibitor of RyRs). Treatment of cells in the fourth day of differentiation from CSC and MSC during 48 h with ryanodine ExC resulted in a significant increase in the proportion of NEL-positive cells while ryanodine InhC decreased this percentage to a level significantly smaller than that found in control conditions (see Table 2 for a summary). Likewise, the percentage of nestin-positive cells increased and decreased with ryanodine ExC or InhC treatment, respectively (Table 2).

In order to further determine if the reduced number of NEL-positive cells in ryanodine InhC-treated cultures is due to the inhibition of neuronal differentiation or/and decreased cell viability, double-immunolabeling for BrdU and NEL or BrdU and nestin were performed for both, ryanodine ExC and InhC concentrations. BrdU would mark the proliferative cells that are neural progenitor cells (nestin-positive) or immature neuron cells (NEL-positive). It was found that ExC treatment promoted an increase on BrdU/NEL-positive cells for both, CSC- and MSC-DN, compared to control and
and if neurogenesis requires Ca\textsubscript{2+} signaling in neurons. However, it is not clear whether RyR-mediated Ca\textsubscript{2+} signaling in neurons. Furthermore the role of IP\textsubscript{3}Rs on neuronal differentiation and proliferation of NPC from CSC and MSC was evaluated as well as if there was any correlation with RyR activation or inhibition. The activity of adenophostin-A (2 nM), an IP\textsubscript{3}R agonist, in NPCs, the presence or absence of ryanodine ExC and InhC were tested. Adenophostin-A and ryanodine ExC promoted an increase of BrdU/NEL-positive cells compared to control without any drug, but with similar results when treated with adenophostin-A alone (Fig. 5B and Table 2). A significant decrease in the percentage of BrdU/NEL-positive cells in ryanodine InhC treatment was observed, and co-treatment with ryanodine InhC and adenophostin-A did not alter this result. This suggests that IP\textsubscript{3}R participates only on differentiation but not on proliferation. The percentage of BrdU/nestin-positive cells treated with adenophostin-A alone presented an increase on NPC of CSC and MSC relative to control. However, treating NPCs with adenophostin-A and ryanodine ExC or InhC induced a significant increase and decrease, respectively, in cells responses (Table 2 and Fig. 5A). These data suggest that adenophostin-A-mediated [Ca\textsubscript{2+}]i elevations induce neuronal differentiation of NPC via a pathway independent of RyR and have effects on the proliferation of immature neurons and NPC.

**RyR guided the L-type Ca\textsubscript{1,1} channel induction neuronal differentiation**

RyRs participate in the control of Ca\textsuperscript{2+} release through channels in the ER and contribute to the dynamics of Ca\textsuperscript{2+} signaling in neurons. However, it is not clear whether RyR- or L-type Ca\textsubscript{1,1} channels-induced [Ca\textsuperscript{2+}]i responses contribute to Ca\textsuperscript{2+} signaling during early neuronal development and if neurogenesis requires Ca\textsuperscript{2+} signaling by RyR or L-type Ca\textsubscript{1,1} channels. We therefore directly analyzed the functional relationship of RyR and L-type Ca\textsubscript{1,1} channels by applying Bay-K 10 μM, a L-type Ca\textsubscript{1,1} agonist, alone and in the presence of ryanodine ExC or InhC (Fig. 5A,B, and Table 2 for a summary). We found that in NPC from both, CSC and MSC cells, Bay-K alone significantly increased the percentage of NEL- and nestin-positive cells, an effect that was inhibited by the co-treatment with ryanodine InhC. The double-immunolabeling for BrdU/NEL-positive and BrdU/nestin only increased or decreased when NPC were co-treated with Bay-K and ryanodine ExC or InhC, respectively. Similar results were obtained with 10 μM nifedipine treatment (Fig. 6A and Table 2), suggesting that tonic activity of L-type Ca\textsubscript{1,1} channels is important for the neuronal differentiation in NPC but not for its proliferation. On the other hand, neither Bay-K nor nifedipine had any effects on the neuronal differentiation in undifferentiated CSCs and MSCs (Fig. 6B and Table 2). The percentage of NEL-positive cells in CSC and MSC cultures in the presence of Bay-K (1.0% ± 0.5% and 0.9% ± 0.3%) or nifedipine (0.8% ± 0.4% and 0.7% ± 0.4%) were not significantly different from control conditions (1.1% ± 0.6% and 0.8% ± 0.4%). These results demonstrate that the activation of L-type Ca\textsuperscript{2+} channel promotes neuronal differentiation through its functional coupling with RyRs, and that RyRs affect proliferation of immature neurons and NPCs.

It has been demonstrated that RyRs can be activated by mobilization of extracellular Ca\textsuperscript{2+} entry through membrane Ca\textsuperscript{2+} channels in neurons [37], so we evaluated the role of Ca\textsuperscript{2+} influx in mediating the neuronal differentiation of NPC from both, CSCs and MSCs, and characterized the functional coupling between RyRs and the regulatory effects of Ca\textsuperscript{2+} influx on neuronal differentiation. We studied the impact of activation of VGCCs on neurogenesis in cultures treated with ryanodine ExC or InhC in the presence of depolarizing extracellular medium by adding KCl (20 mM). The proportion of NEL-positive cells was increased in conditions with depolarizing medium but decreased when it was co-treated with ryanodine InhC or nifedipine (5 μM) (Table 2). The co-treatment with KCl and nifedipine in the presence of ryanodine ExC or ryanodine InhC led to a significant increase and decrease, respectively, on the percentage NEL-positive cells. These data indicate that RyRs play a common role in neurogenesis in different cell lines, such as CSCs and MSCs, by increasing [Ca\textsubscript{2+}]i, triggered by activation of L-type Ca\textsuperscript{2+} channels.

**Discussion**

Spontaneous [Ca\textsubscript{2+}]i oscillations constitute a hallmark of developmental networks. They have been observed in several neural structures including the retina [38], neocortex [39], hippocampus [40], and spinal cord [41]. Although this spontaneous activity plays a key role in the control of neuronal differentiation and synaptogenesis, very little is known about the cellular and molecular events underlying these phenomena during neuronal differentiation.

We further studied the role of [Ca\textsubscript{2+}]i oscillations in differentiation using embryonal CSCs and adult MSCs. Initially we demonstrated expression of RyRs in early embryonal carcinoma and mesenchymal adult stem cells for the first time. These receptors and the VGCCs are likely responsible for the calcium-induced calcium release (CICR) controlling the spontaneous [Ca\textsubscript{2+}]i events. The present data show a transient CICR mechanism in both CSCs and MSCs, involving ER receptors (IP\textsubscript{3}Rs and RyRs) and plasma membrane L-type channels. The presence of classic RyRs was detected by the caffeine-induced [Ca\textsubscript{2+}]i increase and its blockade by Rya InhC (10 μM ryanodine). Furthermore, the caffeine-induced [Ca\textsubscript{2+}]i responses were abolished by the L-type channel blocker nifedipine. While N\textsubscript{o} (ω-CgTX) and P/Q-type (ω-MVIIC) blockers presented no effects on CSC, a small effect was promoted by the N-type blocker on MSC. It is worth mentioning that nifedipine does not pass through the plasma membrane, so it cannot interact directly with RyRs [42]. Thus, our data reveal a functional coupling between Ca\textsubscript{1,1} L-type channels and RyRs in neurons [37,43], but not in undifferentiated CSC and MSC.

The involvement of IP\textsubscript{3}Rs in the mobilization of calcium from intracellular stores was also evaluated. The results demonstrate that XeC completely abolished the [Ca\textsubscript{2+}]i increase induced by the SERCA pump inhibitor CPA, thus
**FIG. 5.** Activation of ryanodine receptors (RyR) promotes neuronal differentiation and proliferation. (A) Representative co-immunostaining for BrdU and nestin (protein marker for neuronal progenitor cells) from carcinoma (CSC) and mesenchymal (MSC) stem cells on the fourth day of differentiation. These cell cultures were pretreated with excitatory ryanodine (Rya ExC, 1 μM) or ryanodine inhibitory (Rya InhC, 10 μM) concentrations for 30 min prior to proliferation induction with adenophostin-A (AdA, 2 nM) or Bay-K (10 μM) over a 48-h period. (B) Cells from the fourth day of differentiation were pretreated with the same drugs as in (A) and were double-immunostained for BrdU and neuronal enolase (NEL, protein marker for mature neurons, green) markers for additional 48 h. Control experiments were carried out in the absence and presence of each drug alone. Plotted data is from three independent experiments with each of them being carried out in triplicates. *p < 0.05, **p < 0.001 compared with control data. (C) Mean values ± SEM percentage of BrdU/nestin-positive cells per field of vision (800 μm²) were determined for experiments in (A). (D) Mean values ± SEM percentage of BrdU/NEL-positive cells per field of vision (800 μm²) were determined for experiments in (B). Twenty to twenty-three fields of vision per cover slip were counted. The shown data are representative of results obtained in three independent experiments. Scale bars in (A) and (B), 50 μm. Figures shown in A and B are from NPC of MSC.

indicating that functional IP₃Rs are present in undifferentiated CSC and MSC and during their neuronal differentiation. These data led us to conclude that IP₃Rs are responsible for early [Ca²⁺]ᵢ elevations in those stem cells. In later stages of the differentiation process, regulation of [Ca²⁺]ᵢ relied on both IP₃- and ryanodine-sensitive stores.
The spontaneous \([\text{Ca}^{2+}]\) oscillations in neuronal differentiation of stem cells are mediated by \(\text{Ca}^{2+}\) entry through L-type \(\text{Ca}^{2+}\) channels. The percentage of \(\text{NEL}\)- and nestin-positive cells is significantly decreased in cultures from ryanodine InhC-treated cultures suggesting that neurogenesis of NPCs from CSCs and MSCs is mediated by \(\text{Ca}^{2+}\) signaling through RyRs. This led us to conclude that \(\text{RyRs}\) affect the generation and proliferation of NPCs and immature neurons. Nevertheless, \(\text{Ca}^{2+}\) entry through L-type \(\text{Ca}^{2+}\) channels is more efficient than through other types of \(\text{Ca}^{2+}\) channels in regulating gene transcription, and thus, in playing a critical role in coupling excitation and transcription in neurons [54]. We also demonstrated that \(\text{Ca}^{1}\) channel modulators can affect \(\text{Ca}^{2+}\) influx through VGCCs during neuronal differentiation. The number of \(\text{NEL}\)- or nestin-positive cells increased after exposure to the L-type channel agonist Bay-K or to the depolarizing agent KCl, while the percentage of positive cells decreased after exposure to the L-type channel antagonist nifedipine. Furthermore, in the presence of nifedipine, the \(\text{NEL}\)- and nestin-positive cells either had a very low \([\text{Ca}^{2+}]\), influx or had no calcium influx in response to

Real-time PCR analysis revealed that gene expression of \(\text{RyRs}\) and IP\(_3\)Rs was already present in CSC and MSC in a lower level with prevalence of the isoforms RyR2 and RyR3, in accordance with a previous study [44]. While RyR1 and RyR2 function as \(\text{Ca}^{2+}\)-release channels, it has been recently demonstrated that RyR3 may negatively regulate RyR2 activity [45]. In undifferentiated CSC and MSC, before inductive of neuronal differentiation, caffeine induced no \([\text{Ca}^{2+}]\), responses coinciding with the low level of expression of the RyR isoforms. It has been suggested that functional interactions between the three isoforms in stem cells may not allow caffeine-induced \([\text{Ca}^{2+}]\), responses, and that RyR2 expression indicates a mature functional phenotype as shown in various brain regions [34].

In vivo experiments studying spontaneous \([\text{Ca}^{2+}]\), oscillations have demonstrated their implication in the regulation of cell death, axon path finding and synaptic pruning [46–48]. Therefore, the molecular and functional developmental events reported in this study are likely to be physiologically relevant. Moreover, further investigations on the mechanisms that control \([\text{Ca}^{2+}]\), in neuronal differentiation of stem cells will increase our understanding of activity-dependent mechanisms in the developing CNS or in neural stem cells from the subventricular zone and the dentate gyrus, which persist in human and may allow the development of strategies for preventing neuronal death in degenerative disorders [49].

### Specific role of RyR on \([\text{Ca}^{2+}]\), signaling during neuronal differentiation of stem cells

The spontaneous \([\text{Ca}^{2+}]\), elevation in neuronal-differentiated stem cells is mediated by diverse pathways such as intracellular \(\text{Ca}^{2+}\) mobilization from \(\text{Ca}^{2+}\) stores by \(\text{RyRs}\) or IP\(_3\)Rs and through extracellular \(\text{Ca}^{2+}\) influx which involves multiple ligand- and voltage-gated channels [50,51]. It has been demonstrated that \([\text{Ca}^{2+}]\), oscillations could be generated by \(\text{RyRs}\) [52,53]. Our results indicate that neuronal differentiation from CSCs and MSCs could be mediated by \(\text{RyRs}\) and that \(\text{RyRs}\) have a key role in promoting spontaneous \([\text{Ca}^{2+}]\), elevation in both cell lines used in this study. Interestingly neurogenesis in ryanodine InhC-treated cultures was significantly reduced, while activation of \(\text{RyRs}\) with caffeine or ryanodine ExC promoted neurogenesis. The percentage of \(\text{NEL}\)- and nestin-positive cells is significantly decreased in cultures from ryanodine InhC-treated cultures suggesting that neurogenesis of NPCs from CSCs and MSCs is mediated by \(\text{Ca}^{2+}\) signaling through \(\text{RyRs}\).
membrane depolarization. This let us to hypothesize that cells may express neuronal markers without acquiring a mature neuronal phenotype [55,56]. The marked inhibition of NPC differentiation induced in our model by nifedipine pretreatment suggests that Ca\(^{2+}\) influx through non-Ca\(_v\)1 channels does not play a significant role in neuronal differentiation. The importance of Ca\(_v\)1 channels in neurogenesis is also reflected by their involvement in the regulation of nestin. Thus, the data obtained with antagonists indicate the involvement of L-type channels through ryanodine receptors in the development of functional neuronal cells in CSC and MSC. Further investigations on the detailed pharmacology of these receptors were beyond the scope of the present study. The contribution of each RyR subtype (RyR1, RyR2, and RyR3) could be identified with in vitro differentiation experiments in which expression of these receptors is specifically downregulated by RNA interference (RNAi). This approach could be used to knock down gene expression of specific ryanodine receptors and in different combinations. Further possibilities in studying the functions of RyRs lie in the development of DNA or RNA aptamers as ryanodine receptor subtype-specific inhibitors [57].

Consistent with these results, we found that although caffeine and ryanodine or KCl and Bay-K still evoked low-level [Ca\(^{2+}\)]\(_i\) activity in ryanodine InhC- or nifedipine-treated cultures, this low-level [Ca\(^{2+}\)]\(_i\) activity is not involved in the activity-induced neurogenesis in undifferentiated CSC and MSC. Thus, an antagonist (nifedipine) and an agonist (Bay-K) of L-type Ca\(^{2+}\) channels were effective in inhibiting and promoting neurogenesis, respectively, only in control and ryanodine ExC culture conditions, but not in ryanodine InhC-treated cultures. These results demonstrate that activity-induced Ca\(^{2+}\) influx through L-type Ca\(^{2+}\) channels, if not powered by a CICR mechanism, is not sufficient to promote neurogenesis. Moreover, our data show that RyRs and IP\(_3\)Rs play, respectively, a major and minor role in mediating the activity-dependent proliferation induced by spontaneous- or neurotransmitter-induced [Ca\(^{2+}\)]\(_i\) elevation, while neurogenesis was mediated by both RyRs and IP\(_3\)Rs. It is known that neurotransmitters, through activation of their respective receptors, trigger specific patterns of calcium transients inside the cell. This process is a prerequisite for the progress of neuronal differentiation [47]. Various receptor subtypes are activated by the same ligand although coupled to different second messengers. These receptors may induce divergent signaling in some cells while activating convergent signaling in other cells. We have previously shown that for cholinergic [18,19] and purinergic receptors [58] the final pathway that induces neurogenesis or proliferation is that mediated by IP\(_3\)Rs and RyRs. Thus, pathways dependent on different neurotransmitters or growth factors would mobilize Ca\(^{2+}\) from ER stores through IP\(_3\)Rs and RyRs. Interestingly, the frequency and amplitude of calcium events can be modulated, directing the acquisition of a defined neuronal phenotype.
